Abstract

We present an unsupervised search for outliers in the Bright Galaxy Survey (BGS) data set from the DESI Early Data Release. This analysis utilizes an autoencoder to compress galaxy spectra into a compact, redshift-invariant latent space, and a normalizing flow to identify low-probability objects. The most prominent outliers show distinctive spectral features, such as irregular or double-peaked emission lines or originate from galaxy mergers, blended sources, and rare quasar types, including one previously unknown broad absorption line system. A significant portion of the BGS outliers are stars spectroscopically misclassified as galaxies. By building our own star model trained on spectra from the DESI Milky Way Survey, we have determined that the misclassification likely stems from the principle component analysis of stars in the DESI pipeline. To aid follow-up studies, we make the full probability catalog of all BGS objects and our pretrained models publicly available.

1. Introduction

Large spectroscopic surveys, such as the Sloan Digital Sky Survey (SDSS; York et al. 2000), have gathered spectroscopic data for millions of astronomical objects. The next generation of surveys, such as the Dark Energy Spectroscopic Instrument (DESI; DESI Collaboration et al. 2016), produce even larger data sets. While the majority of cataloged objects can be classified using known spectral types, there also exist "unknown unknowns"—rare phenomena or object types that deviate from established physical models. In such cases, unsupervised machine-learning methods can identify features in the data without relying on predefined labels or predetermined templates. Such methods are particularly valuable for detecting outliers, which are, by definition, rare and often unexpected.

In this work, we search for outliers in the Early Data Release (EDR; DESI Collaboration et al. 2023a) of the DESI Bright Galaxy Survey (BGS; Hahn et al. 2023), which we briefly describe in Section 2. We employ the spectrum autoencoder (AE) architecture SPENDER introduced by Melchior et al. (2023). This technique compresses galaxy spectra into a compact, redshift-invariant latent space, representing the "type" of galaxies, and makes full use of the observed spectra across all redshifts. Following the approach of Liang et al. (2023), we interpret the sample density in the AE latent space as a probability distribution and identify outliers as low-probability objects using a normalizing flow (NF) model. We describe this approach in Section 3.

Our previous application of this method to SDSS galaxy spectra uncovered a range of astrophysical and instrumental outliers, including blends of multiple galaxies and/or stars, extremely reddened galaxies, as well as stars that had been misclassified as galaxies (Liang et al. 2023). With the new

DESI data set, we again expect outliers to correspond to galaxies in unusual physical states. We also expect them to reveal failures or artifacts of the data processing pipelines and therefore serve as an alternative mechanism for quality control, sensitive to problems that were not even known to be problems.

In Section 4, we present and discuss the nature of remarkable outliers in the BGS galaxy sample, including merging galaxies and rare quasars. Our visual inspection also reveals a substantial fraction to be misclassified stars. In Section 5, we extend our generative modeling approach to stellar spectra from the DESI Milky Way Survey (MWS; Cooper et al. 2023) and identify the likely reason why some BGS galaxies were misclassified. We conclude in Section 6 with a discussion of the limitations and potential extensions of this study.

2. Data

We use data from the DESI EDR, which includes spectra observed during the Survey Validation (SV) campaign that was conducted before the start of the main survey to evaluate DESI's scientific program (DESI Collaboration et al. 2023b). SV was divided into two main phases: an initial "Target Selection Validation" phase to finalize the target selection and a pilot survey of the full DESI program that covered $\sim\!140~{\rm deg}^2,$ the One-Percent Survey.

In this work, we focus on targets from the BGS and the MWS. The initial target lists are defined on the basis of the imaging data from the Legacy Surveys (LS; Dey et al. 2019). An object is considered a BGS target if it is either not in the Gaia Data Release 2 catalog (Gaia Collaboration et al. 2018) or if it is in Gaia and has $(G_{\text{Gaia}} - r_{\text{raw}}) > 0.6$, where G_{Gaia} is the G-band magnitude from Gaia and r_{raw} is the LS r-band magnitude without galactic extinction correction. Afterward, a fiber-magnitude cut is imposed to remove imaging artifacts or other spurious objects. Quality cuts then remove any object without photometric observations in all three LS optical bands and with colors outside -1 < (g-r) < 4 and -1 < (r-z) < 4. Very bright objects with r > 12 and $r_{\text{fibertot}} < 15$ are also

Figure 1. Our approach combines an AE for spectrum reconstruction and an NF for probability estimation. The AE compresses an observed galaxy spectrum into a low-dimensional latent representation of the restframe spectrum, and the NF transforms the latent distribution of the entire BGS galaxy sample into a Gaussian base distribution for efficient probability computation and sampling.

removed from the sample. For further details on the BGS target selection, see Hahn et al. (2023).

MWS targets consist of objects that are in both LS and Gaia Early Data Release 3 (Gaia Collaboration et al. 2021). They are restricted to objects that are classified as point sources based on their morphology and within the magnitude limits 16 < r < 19.2 and $r_{\rm raw} < 20$. There is an additional cut on Gaia astrometric excess noise (Gaia AEN < 3) as well as quality cuts on the LS g- and r-band photometry. No quality cuts on z-band photometry are imposed. For further details on the MWS target selection, see Cooper et al. (2023).

All spectra in the EDR are reduced using the "fuji" version of the DESI spectroscopic data reduction pipeline (Guy et al. 2023). First, spectra are extracted from the spectrograph charge-coupled devices (CCDs) using the spectroperfectionism algorithm of Bolton & Schlegel (2010). Then, fiber-to-fiber variations are corrected by flat-fielding, and a sky model, empirically derived from sky fibers, is subtracted from each spectrum. Afterwards, the fluxes in the spectra are calibrated using stellar model fits to standard stars. The calibrated spectra are coadded across exposures to produce the final processed spectra. Among the different coadds in the EDR, we use the ones produced by combining all available spectra for a given target.

For each spectrum, the DESI EDR provides redshift measurements from the $Redrock^3$ redshift fitting algorithm. For a given spectrum, Redrock derives redshift by minimizing the χ^2 between the observed spectrum and a model spectrum constructed from a linear combination of principal component analysis (PCA) basis spectral templates in three template classes ("stellar," "galaxy," and "quasar"). The redshift and template class that produces the lowest χ^2 is used as the best-fit redshift and spectral classification. Redrock also provides an estimate of redshift uncertainties, ZERR, and a redshift confidence measurement, $\Delta\chi^2$, which corresponds to the difference between the χ^2 values of the best-fit model and the next-best-fit model.

For BGS, we only use spectra observed with functioning fiber positioners and with reliable redshift measurements as defined in Hahn et al. (2023). We only keep spectra classified as galaxy spectra by Redrock (i.e., SPECTYPE == `GALAXY'') with redshifts $z \in [0, 0.8]$ (cutting off a very minor high-redshift tail) and having no

Redrock warning flags ZWARN. From MWS, we select spectra with ZWARN == 0 and SPECTYPE == ``STAR.''

With those cuts, we compile approximately 250,000 BGS and 210,000 MWS spectra. The observed wavelength range is $\lambda_{\rm obs} = 3600...9824$ Å. We split the samples into training, validation, and testing sets, each accounting for 70%, 15%, and 15% of the entire samples, respectively. We adopt the inverse-variance weights and masks from the DESI EDR as data weights (w). We apply an additional mask to the top ~ 100 telluric lines, assigning zero weights to all bins within 5 Å of the line centers, which amounts to approximately 25% of the data vectors. The spectra are then normalized by the median flux over the rest-frame wavelengths $\lambda_{\rm rest} = 5300...5850$ Å, a region that is relatively quiescent and accessible at all redshifts, thereby avoiding redshift-dependent encoding.

3. Methods

Our general approach follows Liang et al. (2023) and is summarized in Figure 1. In short, we train the spectrum AE architecture SPENDER (Melchior et al. 2023) on the observed BGS spectra. That means we encode a spectrum $x \in \mathbb{R}^M$ into a small number of latent variables $s \in \mathbb{R}^S$. For this work, we set S=6. From these latents, the decoder produces a restframe model x', which is redshifted and resampled to produce an observed-frame reconstruction x'' that matches the observation. In the first training phase, we adjust the network weights so as to minimize the fidelity loss, which quantifies the reconstruction quality over batches of N spectra:

$$L_{\text{fid}} = \frac{1}{2\text{NM}} \sum_{i}^{N} \mathbf{w}_{i} \odot (\mathbf{x}_{i} - \mathbf{x}_{i}''(\mathbf{x}_{i}, z_{i}))^{2}, \tag{1}$$

where x_i and x_i'' denote the input spectrum and its observedframe reconstruction z_i is the known redshift of source i, w_i is the inverse variance weights from EDR with telluric masks, and \odot is the element-wise multiplication. For Gaussiandistributed noise, this loss measures the mean log-likelihood of data given the AE model.⁴

In the second phase, we train with the fidelity loss and two extra losses that make the latent space distribution

https://redrock.readthedocs.io

⁴ As described by Guy et al. (2023), the flux errors provided by the EDR are uncorrelated with wavelength and well-approximated by Gaussian distribution. While we recognize that real flux errors may show some deviations from perfect Gaussianity, our framework can adapt to alternative noise distributions by changing the likelihood model in the loss function.

Figure 2. BGS galaxy spectra (black) and their reconstructed models (red) as determined by our spectrum AE. The main panels present the entire flux-normalized restframe spectrum, assuming the *Redrock* redshift, with regions masked during training shaded in gray. The upper left panels provide zoomedin views of significant emission/absorption lines, while the upper right panels show the image of the source from the DESI Legacy Imaging Surveys with the fiber size indicated in red.

approximately redshift-invariant. This property yields a more physically meaningful latent distribution and has proven effective for finding outliers in SDSS spectra (Liang et al. 2023). The first extra loss term ensures that spectra that are close in data space are also close in latent space; the second one promotes proximity in latent space between the original spectrum and an augmented version, where we modified the redshift and added additional noise to the spectrum (see additional details about loss functions in Liang et al. 2023).

Upon convergence of our two-phase training, we achieved fidelity losses of 0.384, 0.391, and 0.386 on the training, validation, and test sets, respectively. The consistency across different data sets indicates that our model is generalizing well on unseen data points, with no evidence of significant overfitting. The achieved fidelity corresponds to a reduced chi-square (χ^2) value of 0.77. Figure 2 presents the reconstructed restframe models for three representative galaxy spectra in BGS. As intended, the model also exhibits redshift invariance. In the latent space of the trained AE model, original

spectra and their artificially redshifted augmentation spectra are, on average, 21 times closer to each other than the average pairwise distance between different objects. This indicates that our model successfully captures the intrinsic characteristics of galaxies, regardless of their redshift.

In Figure 2, the reconstructed spectra exhibit larger spreads at both the shortest and longest wavelengths. This behavior results from the lack of extremely high and low redshift samples in our data set. In these regions, the under-constrained model produces many "spikes," which gravitate toward 1—the default value from the decoder's initialization. While this suggests that model predictions at the edges of the wavelength range should be used with caution, the central rest-frame range, where the bulk of the galaxy spectra lie, is reliably captured by our model.

As the last step, we train a specific type of NF (Tabak & Vanden-Eijnden 2010; Tabak & Turner 2013) model known as a Masked Autoregressive Flow (MAF; Papamakarios et al. 2017) to describe the density of galaxies in the AE latent space. The combination of an AE and an NF is synergistic. The NF provides a flexible density estimator for the complex latent distributions AEs tend to form, while the AE serves as a nonlinear compression scheme to provide a lower-dimensional space for the NF to operate in. Because of our extended training procedure, the latents are approximately invariant under changes of redshift, rendering them much more informative conditioning variables to describe intrinsic galaxy properties than the observed spectrum data vector. With the AE-NF combination, we can evaluate the probability $p_{\text{galaxy}} = p(\mathbf{x}|\text{BGS})$ of any spectrum \mathbf{x} to be drawn from the BGS sample. Spectra with low p_{galaxy} can thus be interpreted as outliers in the galaxy sample.

4. BGS Outliers

We defined an outlier score as $-\log p_{\rm galaxy}$ and carried out a visual inspection of the top 200 outliers. During our inspection, we employed a nonexclusive labeling approach, acknowledging that a single object can manifest multiple outlying behaviors and be tagged with several labels. For a complete list of these outliers, including their DESI ID, R.A., decl., outlier score, and visual labels, we direct the reader to Table 1 in the Appendix. A selection of these outliers is shown in Figure 3.

We identified velocity structures in 61 objects (30.5%). A significant fraction of the outliers are stars: 32 misclassified individual stars, 3 star pairs, and 5 star-galaxy blends. We also found 17 quasars (8.5%), including 2 unusual broad absorption line (BAL) quasars. Calibration or sky-subtraction anomalies were detected in 37 cases (18.5%). Wolf–Rayet signatures and [N I] λ 5200 emissions were present in 42 (21%) and 27 (13.5%) of the objects, respectively. Narrow emission lines are observed in 17 cases (8.5%), 12 of which are extragalactic H II regions. Extreme starbursts, characterized by a distinctive blue continuum shape dominated by early-type stars, are detected in 26 (13%) objects. A smaller fraction of galaxies exhibited strong H δ absorption (1%), extremely reddened continua (2%), or galaxy superposition features (1.5%). We found eight instances (4%) where the continuum seemed unusual for unclear reasons. Lastly, 1.5% of the outliers remained unidentified. The total exceeds 100% due to the multiple labels an object can receive.

Notes.

(This table is available in machine-readable form.)

4.1. Velocity Structure

Velocity structures, loosely defined by irregularly shaped emission lines in their spectra, stand out as a dominant outlier type. A fraction of these outliers show double-peaked narrow emission lines (e.g., outlier 9,⁵ shown in the second row of Figure 3), indicating that the spectra contain overlapping galaxies in cluster environments or galaxy mergers. Another example not shown in the figure, outlier 125, reveals two distinct sets of emission lines, and the DESI imaging data are consistent with a galaxy merger. Double-peaked narrow emission lines can arise due to complex kinematics in the narrow-line region surrounding a single AGN induced by outflows or disk rotation, or the presence of two separate narrow-line regions associated with two merging AGN at small relative velocities (Shen et al. 2011). Among the objects showing double-peaked emission lines, most galaxies have settled galaxy morphologies and no obvious mergers, making them candidates for close separation dual AGN in the late stages of the merger. The emission-line ratio diagnostics seem to offer some support for this hypothesis: of the 13 systems with double-peaked emission lines, 7 align with AGN classifications, which will be discussed in more detail below.

We further characterize these outliers using their emission-line ratios. The equivalent widths of prominent emission lines, such as [N II], [O III], [S II], H\$\alpha\$, and H\$\beta\$, were determined by fitting Gaussian profiles to the observed lines at fixed wavelengths and then integrating over these best-fit profiles. Following the classification scheme of Kewley et al. (2001), objects that lie above the empirical boundaries on the [N II]/H\$\alpha\$ versus [O III]/H\$\beta\$ and [S II]/H\$\alpha\$ versus [O III]/H\$\beta\$ diagrams were classified as "AGN" type. We found that 32\$^6\$ out of 61 objects align with AGN classifications in the Baldwin-Phillips-Terlevich (BPT) diagram.

A fraction of the sample is characterized by significantly broadened emission lines (FWHM >800 km s⁻¹). Such

broadened emission lines can act as observational proxies of powerful AGN-driven outflows. For example, outlier 37 (Transient Name Server (TNS) AT2020dig) shows complex structures near the ${\rm H}\alpha$ and [O III] emissions involving multiple broad components that exceed 1000 km s⁻¹. This system was reported on the TNS (Nordin et al. 2020) due to the detection of AGN-like optical variability in time-domain imaging from the Zwicky Transient Facility (Bellm et al. 2019; Graham et al. 2019).

Lastly, some outliers demonstrate asymmetric emission lines -signatures of complex gas kinematics. For example, outlier 20 exhibits additional structure to the blue of its emission line centers. This is consistent with the DESI imaging data, which shows a close galaxy pair with evident tidal deformations. Furthermore, these observations align well with the system's prior classification as a galaxy merger by De Propris et al. (2007). Outlier 11 (SDSS J135331.57+042805.2, z = 0.14) stands out with asymmetric emission lines coupled with a reddened continuum. Its high star formation rate $(SFR = 221.86 \ M_{\odot} \text{yr}^{-1}; \text{Lai et al. } 2020)$ positions it well above the star formation main sequence at low redshift (Lee et al. 2015; Renzini & Peng 2015). Such intense star formation is likely the primary driver behind its bright polycyclic aromatic hydrocarbon emission (Lai et al. 2020). Additionally, the reddened continuum and tidal features in the DESI imaging are consistent with its identification as an ultraluminous infrared galaxy undergoing a merger (Kim et al. 2002). In contrast, outlier 60 displays a combination of blue-skewing [O III] emission profile, Wolf-Rayet signature, and an extremely blue continuum in its optical spectrum. These spectral characteristics suggest ongoing starburst and AGN activity, which align with its recognition as a radio-loud AGN by Kozieł-Wierzbowska et al. (2020).

4.2. Quasar

In the top 200 BGS galaxy outliers, we visually identified 17 quasars. This group comprises two BAL quasars and one red/dust-obscured quasar. The *Redrock* pipeline should have tagged such objects as QSO but did not, so we expect these misclassifications to be somewhat unusual quasars.

^a Kim et al. (2002).

^b De Propris et al. (2007).

^c Liu et al. (2015).

^d Nordin et al. (2020).

^e Kozieł-Wierzbowska et al. (2020).

f Capetti et al. (2022).

g Best & Heckman (2012).

⁵ When specific outliers are referred to by number (e.g., "outlier 6"), this number denotes their rank based on outlier scores. Identification and coordinates can be found in Table 1.

Objects with AGN activities might not be identified in the BPT diagram if certain lines are inaccessible or if the line profiles are highly non-Gaussian.

Figure 3. Representative selection of outliers in BGS identified by the galaxy AE and normalizing flow, in decreasing order of the outlier score (details for each object in Section 4). The panels are identical to Figure 2, but for visual clarity, we omitted showing the AE model. The legend in the upper left corner includes the DESI Target ID, *Redrock* redshift, reduced chi-square of the AE model, and the negative log probability of the NF model. The red dashed lines in the bottom panel indicate prominent features of a suspected broad absorption line quasar at z = 1.53.

Previously unreported, outlier 111 (fifth row in Figure 3) is characterized by a red/dust-obscured continuum and distinct blue-skewing emission lines, indicating the presence of strong outflows. Its spectral profiles resemble those observed in extremely red quasars (ERQs; Ross et al. 2015; Zakamska et al.

2016). Although this object's broadband color r - W4 = 12.22 is not quite as extreme as the previous ERQ criteria (r - W4 > 14), where W4 refers to the Vega magnitude in the WISE W4 filter), it is also fainter and toward the low end of the redshift range covered earlier. Its fainter luminosity and lower

redshift align it more closely with the dust-reddened quasars presented by Glikman et al. (2012). In any case, line shapes and photometric properties suggest strongly accelerated gas with high levels of dust obscuration.

Among the two BAL quasars, outlier 29 was recognized as a low-ionization BAL QSO (LoBAL) by Liu et al. (2015). Previously unknown, outlier 115 (last row in Figure 3) has complex and broad absorption features. The Redrock redshift estimate of z = 0.0698 would render the H α region highly unusual. Instead, we believe that this source is in fact a BAL (Hall et al. 2002) quasar at z = 1.53. This is supported by the presence of deep absorption troughs blueward of Mg II λ 2800, C III] λ 1909, Al III λ 1860, and C IV λ 1549. This object bears a resemblance to iron low-ionization BAL quasars (FeLoBALs; Reichard et al. 2003; Choi et al. 2022), a rare subtype of LoBAL quasars that show broad iron absorptions. These FeLoBALs might represent a short-lived transitory phase evolving from young, dust-shielded quasars to more common ones (Farrah et al. 2007), but the origin of the strong absorption lines is still poorly understood.

4.3. Unusual Emission Lines

We identified 42 galaxies that show narrow He II λ 4686 emission lines (e.g., outlier 2) or broad emission features at the He II (e.g., outlier 19); both can be interpreted as signatures of Wolf–Rayet stars. Unsurprisingly, the Wolf–Rayet signatures are strongly correlated with extreme starbursts (indicated by the extremely blue continuum) and velocity structures (suggests galactic wind or AGN activity). Previous studies have also reported observations of Wolf–Rayet features in AGNs (Kunth & Contini 1999; Lipari et al. 2003; Brinchmann et al. 2008).

Additionally, the [N I] λ 5200 emission line, usually observed in planetary nebulae, was detected in 27 objects, including outlier 9 shown in Figure 3. It also correlates with the aforementioned velocity structures and starburst.

4.4. Extremely Blue/Red Objects

We found that 26 of the top 200 BGS outliers are characterized by an extremely blue continuum, which indicates extreme starbursts. The typical continuum slope for these extremely blue galaxies, obtained by fitting their continuum to a power law $f_{\lambda} \propto \lambda^{\beta}$, falls between $-2.5 < \beta < -1$. For context, $\beta = -1$ represents the 0.1% percentile in the BGS galaxy sample. In contrast, only four objects show an extremely reddened continuum. Outlier 83 exhibits such an extreme reddening in its continuum that no emission line bluer than $H\alpha$ is detected. The corresponding imaging data reveal that the galaxy is in an edge-on orientation with visible dust lanes.

Narrow emission lines (<100 km s⁻¹) are observed in 17 objects (8.5%), and in 12 cases, the imaging data show that they are extragalactic H II regions in nearby galaxies.

4.5. Strong H\dagand Absorption

Poststarburst galaxies, commonly known as E+A galaxies, exhibit strong Balmer absorption lines, particularly $H\delta$ absorption. These galaxies have recently experienced a burst of star formation that has subsequently ceased (Goto 2007). Given the transient nature of A-type stars, the E+A phase is

short-lived in the context of galaxy evolution (Baron et al. 2018).

In our sample, we identified two such galaxies with strong ${\rm H}\delta$ absorption: outlier 54 (at $z\!=\!0.51$) and outlier 71 (at $z\!=\!0.76$). Notably, both galaxies also present broad [O III] emissions. Specifically, outlier 54 features a "blue wing" adjacent to the [O III] emission, indicative of strong outflow. AGN feedback is proposed as a primary mechanism responsible for terminating star formation in galaxies by expelling the galaxy's remaining gas. The detection of AGN-driven outflows in outlier 54 offers potential evidence of this feedback in action and provides opportunities for further investigation into the feedback process.

4.6. Calibration/Sky-subtraction Issues

Calibration issues, with either a single arm missing or different arms being improperly aligned (e.g., for outlier 4), are detected in 36 objects. A sky-subtraction issue is detected in one object, outlier 90, where a significant portion of flux values are negative.

4.7. Blends

We found a variety of blended objects, similar to the SDSS galaxy outliers we reported in Liang et al. (2023). We present an interesting case, outlier 34, in the fourth row in Figure 3, showing a chance alignment of an M-type star and a distant galaxy merger at z=0.13. We also see star pairs (e.g., outlier 1, first row in Figure 3), a galaxy pair (outlier 125), and a quasar pair (outlier 15).

4.8. Misclassified Star

Among the top 200 outliers in the BGS galaxy sample, the largest group of nongalactic objects consists of 35 stars, including 32 individual stars and 3 star pairs. Outlier 1 (first row of Figure 3) presents the combined spectral features of a K-type star (the Mg b absorption feature) and an M-type star (the red continuum). However, like outlier 14 (third row of Figure 3), many stars we found show no indication of blending and are bright enough to reveal the diffraction spikes and saturate the LS images. We suspect that their brightness led to biases in the imaging measurements, including the estimation of size, which made these objects appear extended and thus targeted in BGS. What surprises us is that *Redrock* classified these sources as galaxies with sufficient confidence (DELTACHI2 > 40), sometimes even placing them at cosmological redshifts.

5. Stellar Spectrum Model

We further investigate the stellar contamination in the galaxy sample. A closer inspection of these stellar outliers shows that *Redrock* finds a plausible fit with its galaxy PCA templates, but shows larger residuals for its star templates (see Figure 4). These residuals resemble the prominent metal oxide (TiO, VO) absorption features in M dwarfs, but the residuals flip sign in different sources. As these features cannot arise in emission, we surmise that either the mean PCA spectrum or the eigenvectors *Redrock* uses for its star fits were trained with an overabundance of M dwarfs, so that these metal oxide bands get imprinted on the models of other stars.

This sample excludes nongalactic objects such as stars and quasars.

Figure 4. Comparison of observed spectra (black) and model fits (*Redrock* galaxy model (cyan), *Redrock* star model (blue), and our star AE model (red)) for two example stars misclassified as galaxies by *Redrock*. Shaded regions indicate areas masked due to telluric contamination.

Figure 5. DESI MWS spectra (black) and their reconstructed models (red) from our star AE. Panels as in Figure 2.

To test this hypothesis we make our own star model by following the generative modeling approach of Section 3 and repeat the AE and NF training with stars in the DESI MWS. The typical quality of the StarAE reconstructions of a representative selection of MWS stars can be seen in Figure 5. We also include the StarAE model in Figure 4, demonstrating that it is not affected by the spurious features of the PCA model. We conclude that SPENDER successfully deals with the diversity in stellar types, variations in radial velocity,

and observational imperfections, and produces an accurate model that is not limited to a linear combination of orthogonal templates.

6. Discussion and Conclusions

In this work, we have identified and cataloged outliers from the DESI BGS with a spectrum AE and a normalizing flow. The overall high quality of DESI spectra allows us to present a rich collection of objects exhibiting unusual physical properties, ranging from irregular or double-peaked emission lines, blended objects, and galaxy mergers, to E+A galaxies with strong outflow, BAL quasars, and reddened quasars. However, our outlier detection scheme has also unveiled issues related to the data collection and processing pipelines. Predominantly, we find BGS outliers to be stars, misclassified by Redrock as galaxies.

This finding prompted the development of our own star model, following the same approach as for galaxies, but now applied to stellar spectra from the DESI MWS. We find good modeling quality without the PCA residuals in the current *Redrock* PCA models. We also identified several more outliers that conform neither with our galaxy nor our star model. These are often blended sources, quasars, or spectra with calibration issues.

To facilitate further studies, we release the full catalog of galaxy and star probabilities and reconstruction qualities for all BGS objects at our code repository. The pretrained AE and normalizing flow models are also accessible with instructions at that URL.

As possible extensions of the work presented here, the pretrained StarAE and StarNF models could be employed to identify unusual stars in the MWS sample for follow-up investigations. It is also entirely possible to create a star–galaxy classifier by running a spectrum through both of our pipelines and then comparing the probabilities from each of the NFs to make classification decisions based on the relative likelihoods.

Acknowledgments

We are grateful for the help of Michael Strauss in interpreting the weirdest spectra we discuss in this work. We thank the anonymous reviewer for the insightful and constructive feedback, which greatly improved the manuscript. We also thank Sicong Lu for assistance in manuscript revision.

This work was supported by the AI Accelerator program of the Schmidt Futures Foundation. The authors are pleased to acknowledge that the work reported on in this paper was substantially performed using the Princeton Research Computing resources at Princeton University, which is a consortium of groups led by the Princeton Institute for Computational Science and Engineering (PICSciE) and Office of Information Technology's Research Computing.
